AN IMPROVED BOUND FOR FIRST-FIT ON POSETS WITHOUT TWO LONG INCOMPARABLE CHAINS

VIDA DUJMOVIĆ, GWENAËL JORET, AND DAVID R. WOOD

ABSTRACT. It is known that the First-Fit algorithm for partitioning a poset P into chains uses relatively few chains when P does not have two incomparable chains each of size k. In particular, if P has width w then Bosek, Krawczyk, and Szczypka (*SIAM J. Discrete Math.*, 23(4):1992–1999, 2010) proved an upper bound of ckw^2 on the number of chains used by First-Fit for some constant c, while Joret and Milans (*Order*, 28(3):455–464, 2011) gave one of ck^2w. In this paper we prove an upper bound of the form ckw. This is best possible up to the value of c.

1. INTRODUCTION

Every partition of a poset P into chains contains at least w chains where w is the maximum size of an antichain in P, called the *width* of P. By a classical theorem of Dilworth [7], there always exists a chain partition of P achieving this lower bound. While such an optimal chain partition can easily be computed (see for instance [21]), this computation requires a full knowledge of the poset P and cannot be made *on-line*: In the on-line setting, elements of P are uncovered one at a time and a chain decomposition of the poset uncovered so far must be maintained at all times. In this model, once an element is assigned to some chain it must remain assigned to that chain during the whole execution.

Szemerédi proved that every on-line algorithm can be forced to use $\Omega(w^2)$ chains (see [1, 14]). It is a well-known open problem to decide whether there exists an on-line algorithm that uses polynomially many chains (in w). The current best bound, due to Bosek and Krawczyk [2], is sub-exponential: $w^{16 \log_2 w}$.

First-Fit is a natural on-line algorithm for partitioning a poset P into chains: Each time a new element v is uncovered, First-Fit puts v into the first chain in the current chain partition such that v is comparable to all elements in that chain. If no such chain is found, then a new chain containing only v is added at the end of the current chain partition.

The performance of First-Fit on various classes of posets has been studied extensively [1, 3, 4, 5, 6, 10, 14, 16, 17, 18, 19, 20]. In particular, Kierstead [14] showed that First-Fit can be forced to use an unbounded number of chains even on posets of width 2. (A description of Kierstead's construction can be found at the end of Section 3.) Nevertheless, First-Fit behaves well on some restricted classes of posets. A prominent example are interval orders, for which Kierstead [15] obtained a linear bound of $40w$, which was subsequently improved by Kierstead and Qin [16] to $25.8w$, and then by Pemmaraju, Raman and Varadarajan [19, 20] to $10w$. It was later shown by Brightwell, Kierstead and Trotter [5] and by Narayanaswamy and Babu [18] that the proof method of Pemmaraju *et al.* actually gives a bound of $8w$. (This refined analysis is also presented in the journal version [20] of [19].) As for lower bounds, the best result to date is that, for every $\varepsilon > 0$, First-Fit can be forced to use at least $(5 - \varepsilon)w$ chains provided w is large enough [17].

By a well-known theorem of Fishburn [12], interval orders are exactly the posets not containing $\mathbf{2} + \mathbf{2}$ as an induced subposet, where $\mathbf{k} + \mathbf{k}$ denotes the poset consisting of two disjoint chains A, B with $|A| = |B| = k$ where every element in A is incomparable to every element in B. It is therefore natural to ask to which extent the good performance of First-Fit on interval orders extends to posets without $\mathbf{k} + \mathbf{k}$ (where $k \geqslant 2$). This question was first considered by Bosek, Krawczyk and Szczypka [4], who proved an upper bound of $3kw^2$ on the number of chains used by First-Fit. Joret and Milans [13] subsequently showed an upper bound of $8(k - 1)^2 w$, which is asymptotically better when k is fixed. Note however that the two bounds are incomparable if k and w are independent variables.

The main result of this paper is that a linear dependency in k and in w can be guaranteed simultaneously: First-Fit partitions every poset of width w without $\mathbf{k} + \mathbf{k}$ into at most $16kw$ chains. We also give an example where First-Fit uses $(k - 1)w$ chains on such posets, implying that our upper bound is within a constant factor of optimal.

Our proof of the upper bound is in two steps. First we prove that the incomparability graph of every poset of width w without $\mathbf{k} + \mathbf{k}$ has small pathwidth, namely pathwidth at most $2kw - 1$. Then we show that the fact that First-Fit uses at most $8w$ chains on interval orders of width w, as proved in [20], implies that First-Fit uses at most $8(k + 1)$ chains on posets whose incomparability graphs have pathwidth k. Combining these two results, we obtain an upper bound of $8 \cdot 2kw = 16kw$ on the number of chains used by First-Fit on posets of width w without $\mathbf{k} + \mathbf{k}$.

2. Definitions

A *chain* (respectively, *antichain*) in a poset P is a set of pairwise comparable (incomparable) elements in P. The maximum size of an antichain in P is called the *width* of P. An element v is *minimal* (respectively, *maximal*) in P if there is no element w in P such that $w < v$ in P ($w > v$ in P).

The *incomparability graph* of a poset P is the graph with vertex set the elements of P where two distinct vertices are adjacent if and only if the corresponding elements are incomparable in P.

A *First-Fit chain partition* of a poset P is a sequence $C_1, \ldots, C_q$ of non-empty disjoint chains of P such that every element of P is in one of the chains, and for each i, j such that $1 \leqslant i < j \leqslant q$ and each $v \in C_j$, there exists $w \in C_i$ such that v and w are incomparable in P. Observe that every chain partition produced by the First-Fit algorithm is a First-Fit chain partition, and conversely every First-Fit chain partition can be produced by First-Fit.

A *First-Fit coloring* of a graph G is a coloring of the vertices of G with positive integers such that every vertex $v \in V(G)$ that is colored $i \geqslant 2$ has a neighbor colored j for every $j \in \{1, \ldots, i-1\}$. The maximum number of colors in a First-Fit coloring of G is denoted $\mathrm{FF}(G)$. Note that a First-Fit chain partition of a poset P can equivalently be seen as a First-Fit coloring of the incomparability graph of P.

Every (finite) set $\mathcal{I}$ of closed intervals of the real line defines a corresponding poset P as follows: P has one element per interval in $\mathcal{I}$, and $u < v$ in P if and only if $I(u) = [a, b]$ and $I(v) = [c, d]$ with $b < c$, where $I(u)$ denotes the interval corresponding to u. The set $\mathcal{I}$ is said to be an *interval representation* of P. A poset P is an *interval order* if and only if P has an interval representation.

Such a set $\mathcal{I}$ also defines a corresponding graph G, namely the intersection graph of the intervals in $\mathcal{I}$. Thus G has one vertex per interval, and two distinct vertices are adjacent if and only if the corresponding intervals intersect. Similarly as above, $\mathcal{I}$ is said to be an *interval representation* of G. A graph is an *interval graph* if it has an interval representation. Clearly, the incomparability graph of an interval order is an interval graph, and conversely every interval graph is the incomparability graph of some interval order.

A *path decomposition* of a graph G is a sequence $B_1, \ldots, B_k$ of vertex subsets of G (called *bags*) such that each vertex of G appears in a non-empty consecutive set of bags, and each edge of G has its two endpoints in at least one bag. The *width* of the decomposition is the maximum cardinality of a bag minus one. The *pathwidth* $\mathrm{pw}(G)$ of G is the minimum width of a path decomposition of G. Note that the pathwidth of G can equivalently be defined as the minimum integer k such that G is a spanning subgraph of an interval graph H with $\omega(H) = k+1$ (where $\omega(H)$ denotes the maximum cardinality of a clique in H).

3. Proofs

A poset P *extends* (or *is an extension of*) a poset Q if P and Q have the same set of elements and $u < v$ in Q implies $u < v$ in P for all elements u, v.

Theorem 3.1. *Every poset P of width w without $\mathbf{k} + \mathbf{k}$ extends some interval order Q of width at most $2kw$.*

Proof. Let $C_1, \ldots, C_w$ be a partition of P into w chains (which exists by Dilworth's theorem). A subset X of elements of P will be called a *block* if $|X \cap C_i| \geqslant \min\{|C_i|, 2k\}$ and the elements in $X \cap C_i$ are consecutive in the chain C_i for every $i \in \{1, \ldots, w\}$. Given a block X, the set $\mathrm{up}(X)$ is defined as the set of all elements y of P such that $y \in C_i - X$ for some $i \in \{1, \ldots, w\}$ and $y > x$ for every $x \in X \cap C_i$. An element $u \in X$ is *good* if $u < v$ in P for every $v \in \mathrm{up}(X)$.

With a slight abuse of terminology, we say that an element u of a set X is *minimal in X* (*maximal in X*) if u is a minimal (maximal, respectively) element of the poset induced by X.

Claim 3.2. *If X is a block with $\mathrm{up}(X) \neq \varnothing$, then there is an index $i \in \{1, \ldots, w\}$ such that $\mathrm{up}(X) \cap C_i \neq \varnothing$ and the minimal element of $X \cap C_i$ is good.*

Proof. Reindexing the chains $C_1, \ldots, C_w$ if necessary, we may assume that there is an index w' such that $\mathrm{up}(X) \cap C_i \neq \varnothing$ if and only if $i \in \{1, \ldots, w'\}$. (Note that $w' \geqslant 1$, since otherwise $\mathrm{up}(X)$ would be empty.)

For every $i \in \{1, \ldots, w'\}$, the set $X \cap C_i$ is a chain of size $2k$; let L_i be the set of the k smallest elements in that chain, and let $U_i := (X \cap C_i) - L_i$. (Note that $|U_i| = k$.) Thus $u < v$ in P for every $u \in L_i$ and $v \in U_i$.

Define a directed graph D with vertex set $V := \{1, \ldots, w'\}$ as follows: For every $i, j \in V$, $i \neq j$, add an arc (i, j) if $u < v$ in P for some $u \in U_i$ and $v \in L_j$. We will also need to record such a pair (u, v) of witnesses for each arc $a = (i, j)$: Let $t(a)$ and $h(a)$ denote elements $u \in U_i$ and $v \in L_j$, respectively, such that $t(a) < h(a)$ in P.

We claim that D has no directed cycle. Arguing by contradiction, suppose that $a_1, \ldots, a_p$ is a directed cycle in D, where a_ℓ denotes the ℓ-th arc of the cycle. Then for every $\ell \in \{1, \ldots, p\}$ we have $t(a_\ell) < h(a_\ell)$ in P (by definition). Also, taking indices modulo p, we have $h(a_\ell) < t(a_{\ell+1})$ in P since $h(a_\ell) \in L_j$ and $t(a_{\ell+1}) \in U_j$, where $j \in V$ is the vertex of D such that $a_\ell = (i, j)$ and $a_{\ell+1} = (j, i')$. Hence $t(a_1) < h(a_1) < \cdots < t(a_p) < h(a_p)$ in P but also $h(a_p) < t(a_1)$, which is a contradiction. Thus D has no directed cycle.

Hence, there exists a vertex $i \in V$ that has no incoming arc in D. Without loss of generality, $i = 1$. Let x be the minimal element of the chain $X \cap C_1$. We now show that x is good.

Clearly, $x < y$ for every $y \in \mathrm{up}(X) \cap C_1$. Since $\mathrm{up}(X) \subseteq C_1 \cup \cdots \cup C_{w'}$, it remains to show that $x < y$ for every $j \in \{2, \ldots, w'\}$ and every $y \in \mathrm{up}(X) \cap C_j$. Let j be such an index, and consider the two disjoint chains L_1 and U_j. Since P has no $\mathbf{k} + \mathbf{k}$ and since $|L_1| = |U_j| = k$, some element $u \in L_1$ is comparable to some element $v \in U_j$. We cannot have $u > v$ in P, because otherwise D would contain the arc $(j, 1)$, contradicting

the fact that vertex 1 has no incoming arcs. Thus $u < v$ in P. In particular $u < z$, where z is the maximal element of the chain $X \cap C_j$. On the hand, by the definition of $\mathrm{up}(X)$, we have $z < y$ in P for every $y \in \mathrm{up}(X) \cap C_j$. Therefore, $x \leqslant u < z < y$ holds for every such y, as desired. $\qquad\square$

Define a sequence $B_1, \ldots, B_q$ of blocks iteratively as follows: Let B_1 be the block obtained by taking the union of the $\min\{2k, |C_i|\}$ smallest elements in chain C_i for every $i \in \{1, \ldots, w\}$. For $j \geqslant 2$, if $\mathrm{up}(B_{j-1}) = \varnothing$ then we stop the process and $B_{j-1} = B_q$ becomes the last block of the sequence. Otherwise, let u be a good element of B_{j-1} as in Claim 3.2, that is, $u \in B_{j-1} \cap C_i$ for some $i \in \{1, \ldots, w\}$ such that $\mathrm{up}(B_{j-1}) \cap C_i \neq \varnothing$. Let v be the smallest element of chain $\mathrm{up}(B_{j-1}) \cap C_i$, and let B_j be the block obtained by setting $B_j := (B_{j-1} - \{u\}) \cup \{v\}$.

Observe that every element u of P appears in consecutive blocks of the sequence $B_1, \ldots, B_q$; let $I(u)$ be the closed interval $[i, j]$ of the real line where $i \leqslant j$ are indices such that u is included in precisely the blocks $B_i, B_{i+1}, \ldots, B_j$ of the sequence. These intervals define an interval order Q on the elements of P, where $u < v$ in Q if and only if $I(u) = [i, j]$ and $I(v) = [i', j']$ with $j < i'$. Every antichain A of Q corresponds to a set of pairwise intersecting intervals. By the Helly property of intervals, the latter intervals share a common point, which implies that there is an index $i \in \{1, \ldots, q\}$ such that $A \subseteq B_i$. Conversely, every block B_i is an antichain of Q. It follows that the width of Q is equal to $\max\{|B_i| : 1 \leqslant i \leqslant w\} \leqslant 2kw$.

Now, if $u < v$ in Q, then $j < i'$ where $I(u) = [i, j]$ and $I(v) = [i', j']$, and in particular $v \in \mathrm{up}(B_j)$ by the definition of the blocks. Since $u \notin B_{j+1}$, it follows that u is a good vertex of B_j, and hence $u < y$ in P for every $y \in \mathrm{up}(B_j)$. In particular, $u < v$ in P. Hence P extends Q, and therefore Q is an interval order as desired. $\qquad\square$

Corollary 3.3. *The incomparability graph G of a poset P of width w without $\mathbf{k} + \mathbf{k}$ has pathwidth at most $2kw - 1$.*

Proof. Using Theorem 3.1, let Q be an interval order of width at most $2kw$ such that P extends Q. Then the incomparability graph H of Q is an interval graph with $\omega(H) \leqslant 2kw$ such that $G \subseteq H$. Therefore, G has pathwidth at most $2kw - 1$. (Note that the sequence $B_1, \ldots, B_q$ of blocks defined in the proof of Theorem 3.1 provides a path decomposition of G of width at most $2kw - 1$.) $\qquad\square$

The poset consisting of w pairwise incomparable chains each of size $k - 1$ has width w and no $\mathbf{k} + \mathbf{k}$, and its incomparability graph is the complete w-partite graph with $k - 1$ vertices in each color class, which has pathwidth $(k - 1)(w - 1)$ (see for instance [11, Lemma 8.2]). Thus, asymptotically, the bound in Corollary 3.3 is within a factor of 2 of optimal.

As mentioned in the introduction, Pemmaraju, Raman and Varadarajan [19] proved that First-Fit partitions every interval order of width w into at most $10w$ chains, and this bound can be decreased to $8w$ [20, 18]. Thus $\mathrm{FF}(G) \leqslant 8\omega(G)$ for every interval graph G. While every graph G with pathwidth k is a spanning subgraph of an interval graph H with $\omega(H) = k+1$, this does not immediately imply that $\mathrm{FF}(G) \leqslant 8(\mathrm{pw}(G)+1)$. Indeed the invariant $\mathrm{FF}(G)$ is not monotone with respect to subgraph inclusion; for instance, observe that $\mathrm{FF}(P_4) = 3 > 2 = \mathrm{FF}(C_4)$. (And to emphasize the point, $\mathrm{FF}(K_{n,n}) = 2$ but $\mathrm{FF}(K_{n,n} - M) = n$, where M denotes a perfect matching of $K_{n,n}$.) However, it turns out that the aforementioned upper bound on $\mathrm{FF}(G)$ in terms of the pathwidth of G holds, as we now show.[1]

First, recall that a *homomorphism* from a graph G to a graph H is a function $f : V(G) \to V(H)$ that maps edges of G to edges of H, that is, $f(u)f(v) \in E(H)$ for every edge $uv \in E(G)$. The graph G is said to be *homomorphic* to H if such a mapping exists.

Theorem 3.4. *Every graph G with pathwidth k is homomorphic to an interval graph H with $\omega(H) \leqslant k+1$ and $\mathrm{FF}(G) \leqslant \mathrm{FF}(H)$.*

Proof. Consider a First-Fit coloring of G with $c := \mathrm{FF}(G)$ colors, and let $V_1, \ldots, V_c$ denote the corresponding color classes (in order). Let G' be an interval graph with $\omega(G') = k+1$ that is a spanning supergraph of G. Let $\mathcal{I} = \{I(v) : v \in V(G')\}$ be an interval representation of G', where $I(v)$ denotes the interval corresponding to vertex v. For each $i \in \{1, \ldots, c\}$, let $W_{i,1}, \ldots, W_{i,n_i}$ denote the components of the graph $G'[V_i]$, and let further $I_{i,j} := \cup\{I(v) : v \in W_{i,j}\}$ for each $j \in \{1, \ldots, n_i\}$. Observe that $I_{i,j}$ is again an interval since $G'[W_{i,j}]$ is connected. Let H be the interval graph defined by the latter intervals, and let $v_{i,j}$ denote the vertex of H corresponding to interval $I_{i,j}$, for each i, j such that $1 \leqslant i \leqslant c$ and $1 \leqslant j \leqslant n_i$.

Let $f : V(G) \to V(H)$ be the function that maps each vertex v of G to vertex $v_{i,j}$ of H where i, j is the unique pair of indices such that $v \in W_{i,j}$. Clearly f is a homomorphism from G to H. Now consider an arbitrary clique C of H. By the Helly property of intervals, there is a point x on the real line that is contained in all the intervals corresponding to vertices in C. For each interval $I_{i,j}$ such that $v_{i,j} \in C$, there is at least one vertex in $W_{i,j}$ whose corresponding interval contains the point x. Thus choosing one such vertex for each vertex in C, we obtain a clique C' of G' with $|C'| = |C|$. It follows that $\omega(H) \leqslant \omega(G') = k+1$.

Finally consider the coloring of H with c colors obtained by letting for $i = 1, \ldots, c$ the i-th color class be $Z_i := \{v_{i,j} : 1 \leqslant j \leqslant n_i\}$. (Observe that this is a proper coloring of H since $I_{i,j} \cap I_{i,j'} = \varnothing$ for $j \neq j'$.) For each i, j such that $1 \leqslant j < i$, each vertex $v \in V_i$

---

[1] It should be noted that the invariant $\mathrm{FF}(G)$ on graphs G of bounded pathwidth has been explicitly considered in [8, 9]. However it appears that the authors implicitly assumed that $\mathrm{FF}(G)$ is monotone with respect to subgraph inclusion when writing that upper bounds on $\mathrm{FF}(G)$ when G is an interval graph with $\omega(G) \leqslant k+1$ immediately carry over to graphs G with $\mathrm{pw}(G) \leqslant k$ (see [8, p. 22] and [9, p. 64]). Note that, by Theorem 3.4, the maximum of $\mathrm{FF}(G)$ over all graphs G with pathwidth at most k is indeed always achieved by some interval graph G.
FIGURE 1. The Hasse diagram of poset P_5. The dotted rectangles represent the chains $\{v_{i,j} : 1 \leqslant j \leqslant i\}$ for each i.

is adjacent in G to some vertex $w \in V_j$, since $V_1, \ldots, V_c$ is a First-Fit coloring of G, and thus $f(v)$ is adjacent to $f(w)$ in H (where f is the homomorphism defined above). Since $f(v) \in Z_i$ and $f(w) \in Z_j$, it follows that every vertex in Z_i has a neighbor in Z_j in H for every i, j such that $1 \leqslant j < i \leqslant c$, that is, $Z_1, \ldots, Z_c$ is a First-Fit coloring of H. Hence $\mathrm{FF}(H) \geqslant c = \mathrm{FF}(G)$, and therefore H is an interval graph with the desired properties. $\square$

Theorem 3.4 and the aforementioned bound of $\mathrm{FF}(G) \leqslant 8\omega(G)$ for interval graphs G imply:

Corollary 3.5. $\mathrm{FF}(G) \leqslant 8(\mathrm{pw}(G) + 1)$ *for every graph G.*

Since a First-Fit chain partition of a poset P can equivalently be seen as a First-Fit coloring of the incomparability graph of P, Corollary 3.3 and Corollary 3.5 together imply the follow result.

Theorem 3.6. *First-Fit partitions every poset P of width w without $\mathbf{k} + \mathbf{k}$ into at most $16kw$ chains.*

The bound in Theorem 3.6 is best possible up to a constant factor. This can be shown by modifying the following construction due to Kierstead [14]: For $q \geqslant 2$, define P_q as the poset on the set of elements $V_q := \{v_{1,1}, v_{2,1}, v_{2,2}, v_{3,1}, v_{3,2}, v_{3,3}, \ldots, v_{q,1}, v_{q,2}, \ldots, v_{q,q}\}$, where $v_{i,j} < v_{i',j'}$ in P_q if and only if $i \leqslant i' - 2$, or $i \in \{i' - 1, i'\}$ and $j \leqslant j' - 1$. See Figure 1 for an illustration.
FIGURE 2. The Hasse diagram of poset $Q_{5,4}$. The copies of P_4 are ordered from bottom-right to top-left.

The poset P_q has width 2, because it has two incomparable elements and V_q can be partitioned into the two chains $\{v_{i,j} : 1 \leqslant j \leqslant i \leqslant q, i \text{ odd}\}$ and $\{v_{i,j} : 1 \leqslant j \leqslant i \leqslant q, i \text{ even}\}$. Consider the ordering of the elements of P_q suggested by their indices, namely $v_{1,1}, v_{2,1}, v_{2,2}, \ldots, v_{q,1}, v_{q,2}, \ldots, v_{q,q}$, which we call the *natural ordering*. Given this ordering, observe that First-Fit assigns element $v_{i,j}$ to the $(i - j + 1)$-th chain. In particular, First-Fit uses exactly q chains in total (as proved by Kierstead [14]).

For $k \geqslant 2$ and $w \geqslant 2$, take the disjoint union of $w - 1$ copies of P_{k-1}, denote by $v_{i,j}^\ell$ the element $v_{i,j}$ in the ℓ-th copy of P_{k-1}, and add the following comparisons between elements from distinct copies: For $1 \leqslant \ell < \ell' \leqslant w - 1$ and $i \neq k - 1$, we have $v_{i,j}^\ell < v_{i',j'}^{\ell'}$. Let $Q_{k,w}$ denote the resulting poset. See Figure 2 for an illustration.

The poset $Q_{k,w}$ has width exactly w. We claim that $Q_{k,w}$ has no $\mathbf{k} + \mathbf{k}$. Arguing by contradiction, suppose that A, B are two disjoint chains in $Q_{k,w}$ of size k that are incomparable. First observe that P_{k-1} has no $\mathbf{k} + \mathbf{k}$, since every element of P_{k-1} is incomparable to at most $k - 1$ others. Thus we may assume that A has two elements that belong to distinct copies of P_{k-1}. Since the set $X := \{v_{k-1,j}^\ell : 1 \leqslant j \leqslant k - 1, 1 \leqslant \ell \leqslant w - 1\}$ induces a poset of height $k - 1$, the sets $A - X$ and $B - X$ are not empty. Moreover, every $u \in A - X$ and $v \in B - X$ belong to the same copy of P_{k-1}, as otherwise they would be comparable; thus $A - X$ and $B - X$ are both subsets of the ℓ-th copy

of P_{k-1} for some $\ell \in \{1, \ldots, w-1\}$. Recall that A has at least one element w that belongs to another copy of P_{k-1}, say the ℓ'-th one. Thus $w \in X$. Let $u \in A - X$ and $v \in B - X$. If $\ell' < \ell$, then u and w are incomparable, contradicting $u, w \in A$. If $\ell' > \ell$, then $w > v$ in $Q_{k,w}$, contradicting the fact that w, v are incomparable. Both cases leading to a contradiction, we deduce that the two chains A, B do not exist.

Now, given the ordering of the elements of $Q_{k,w}$ obtained by concatenating the natural orderings of the $w-1$ copies of P_{k-1} in order, First-Fit assigns element $v_{i,j}^\ell$ to the $((k-1)(\ell-1)+(i-j+1))$-th chain, as is easily checked. Hence First-Fit uses $(k-1)w$ chains in total.
